Summary

Loss of ζ-associated protein 70 (Zap70) results in severe immunodeficiency in humans and mice because of the critical role of Zap70 in T-cell receptor (TCR) signalling. Here we describe a novel mouse strain generated by N-ethyl-N-nitrosourea mutagenesis, with the reduced protein stability (rps) mutation in Zap70. The A243V rps mutation resulted in decreased Zap70 protein and a reduced duration of TCR-induced calcium responses, equivalent to that induced by a 50% decrease in catalytically active Zap70. The reduction of signalling through Zap70 was insufficient to substantially perturb thymic differentiation of conventional CD4 and CD8 T cells, although Foxp3+ regulatory T cells demonstrated altered thymic production and peripheral homeostasis. Despite the mild phenotype, the Zap70A243V variant lies just above the functional threshold for TCR signalling competence, as T cells relying on only a single copy of the Zap70rps allele for TCR signalling demonstrated no intracellular calcium response to TCR stimulation. This addition to the Zap70 allelic series indicates that a rate-limiting threshold for Zap70 protein levels exists at which signalling capacity switches from nearly intact to effectively null.

Keywords: Foxp3; N-ethyl-N-nitrosourea mutagenesis; protein stabilization; T cell; T-cell receptor; Zap70.

Introduction

From the recent explosion of human exome sequencing experiments it is becoming increasingly apparent that every individual inherits a high mutational burden, with hundreds of rare mutations that may affect protein sequences and have a major effect on the incidence of human immune disorders.1 Within the rare mutation pool, far more common than ‘knockout’ mutations are point mutations that retain at least some protein function, and yet the effect of hypomorphs is poorly understood because of a primary focus on knockout mouse models. Additional complexity to the genetic context is created by combinatorial variation, because outside consanguineous families the probability of rare mutation compound heterozygosity is greater than rare mutation homozygosity. The potential importance of rare mutations to human health makes it essential to extend the phenotype analysis of mouse models to both hypomorphs and heterozygous interactions of multiple hypomorphic alleles.1,2

A major protein at the crossroads between immunity and tolerance is the tyrosine kinase ζ-associated protein 70 (Zap70), which plays an essential role in activating downstream signal transduction upon T-cell receptor (TCR) engagement. These Zap70-induced signalling pathways are central to T-cell differentiation, activation and proliferation, with a loss of Zap70 in mice resulting in the absence of CD4+ and CD8+ T cells and hence severe combined immunodeficiency (SCID).3–5 Zap70-deficient patients present with a similar absence of CD8+ T cells, but CD4+ T cells are present in normal numbers, albeit of non-functional nature.6 The difference between the mouse and human Zap70/ZAP70-null phenotypes lies in

Abbreviations: APC, allophycocyanin; ENU, N-ethyl-N-nitrosourea; PE, phycoerythrin; PerCP, peridinin chlorophyll protein; Rps, reduced protein stability; SP, single positive; TCR, T-cell receptor; Treg, regulatory T
the ability of SYK to partially compensate for ZAP70-deficiency during thymic differentiation of human CD4+ T cells,7,8 however, SYK cannot compensate for ZAP70 deficiency in peripheral T cells, leading to the same functional outcome of SCID in mice and humans.

Studies of a series of hypomorphic Zap70 mutant mice with graded defects in TCR signalling significantly extended the understanding of the fine-tuned balance between tolerogenic and immunogenic signalling in T cells by revealing phenotypes that would not be predicted based on the simple SCID phenotype of knockout mice. Indeed, in various hypomorphic mutant strains, immune deficiency was associated with immune hyper-activation and/or autoimmunity, ranging from hyper-IgE,9,10 anti-deficiency was associated with immune hyper-activation based on the simple SCID phenotype of knockout mice. Cells by revealing phenotypes that would not be predicted between tolerogenic and immunogenic signalling in T extended the understanding of the fine-tuned balance with graded defects in TCR signalling significantly

Foxp3GFP and bred to C57BL/6 male mice were treated with 100 mg/kg ENU-DNA9 and the second-generation offspring, which were in turn spring were bred back to Foxp3GFP mice are described in the accompanying paper 16. To generate the Zap70P4T mutant mouse strain generated by -ethyl-N-nitrosourea (ENU) mutagenesis, Zap70P4T mice. The reduced protein stability mutation results in an A243V change, which causes a ~55% reduction in Zap70 protein levels. Here we demonstrate that a 55% reduction in functional Zap70 protein results in only mild TCR signalling and cellular phenotypes, whereas a further 50% reduction in Zap70 protein levels generated by compound heterozygosity of hypomorphic alleles demonstrates near-normal positive selection but no peripheral intracellular calcium responses to TCR stimulation. These data demonstrate that combinatorial association of multiple hypomorphic alleles can generate unexpected phenotypes once the net genetic burden rises above set thresholds.

Materials and methods

Mice
Foxp3GFP mice15 were backcrossed to the C57BL/6 background. Zap70P4T mice are described in the accompanying paper 16. To generate the Zap70P4T strain, founder C57BL/6 male mice were treated with 100 mg/kg ENU and bred to Foxp3GFP females. First-generation male offspring were bred back to Foxp3GFP females to produce the second-generation offspring, which were in turn inter-crossed to produce the third generation for phenotype screening. Phenotypic screening involved flow cytometric analysis for CD4 (anti-CD4 antibody) and Foxp3 (GFP), and identification of individuals with values for the percentage of GFP+ cells within the CD4+ population that were more than two standard deviations from the norm. The identified variant offspring were inter-crossed to produce the C57BL/6.Foxp3GFP.Zap70P4T mutant mouse strain. Experimental mice were age-matched and housed under specific pathogen-free conditions. All mice were used after ethics approval of the University of Leuven mouse facility.

Molecular biology

The rps mutation identified by all-exome sequencing was confirmed by Sanger sequencing. Using primers that flank the rps mutation (forward primer 5′-GAC GGT GCT GGC AAG TAC TGC ATC-3′ and reverse primer 5′-TGT CAC GTG TCA ACG AGG TG-3′) a 400-bp fragment was amplified and cloned into the pCR®4-TOPO® vector (Invitrogen, Carlsbad, CA) for sequencing. The Zap70P4T mice were genotyped using the Amplifluor SNP genotyping assay based on PCR amplification with tailed allele-specific primers, a common reverse primer and fluorescence-labelled (JOE-FAM) Amplifluor universal primers (Millipore, Billerica, MA). Primers were designed with the ASSAYARCHITECT software (Millipore) and were 5′-GA AGG TCG GAG TAC ACG GT TGG GAG TAC CTG CTT ACG AGT ACG GC-3′ (wild-type), 5′-GAA GGT GAC CAA GTT CAT GCT GTG GAG TAC -3′ (rps) and the common reverse primer was 5′-CTG TGG GGA CAG ACC TCC TT-3′. Fluorescence end-point measurement was performed using the Taqman RT-PCR 7300 (Applied Biosystems, Foster City, CA).

CD4+ CD8− and CD4− CD8+ splenocytes were sorted after enrichment with an EasySepTM Mouse T Cell Isolation Kit (Stemcell Technologies, Vancouver, BC, Canada). RNA was purified using an RNeasy micro kit (Qiagen, Hilden, Germany) and was reverse transcribed with random hexamers (Life Technologies, Carlsbad, CA) and M-MLV (Invitrogen). Quantitative PCR was performed with the StepOnePlus (Life Technologies) and TaqMan Fast Universal PCR Master Mix (Life Technologies) for Zap70 (Mm.PT.56a.12463755, IDT DNA) and β-actin (Mm.PT.56a.33540333, IDT DNA). Relative gene expression was determined by the 2ΔΔCt method17 and normalized to the average of wild-type CD4+ T cells.

Flow cytometry

Cell surface staining and flow cytometric analysis were performed using the following antibodies: anti-B220-phycoerythrin (PE) -Cy5 (1/400) (RA3-6B2) or PE-Cy7 (1/400) (RA3-6B2), and anti-CD3e-allophycocyanin (APC) (1/400) (145-2c11), anti-CD4-APC (1/400) (GK1.5) or APC-H7 (1/400) (GK1.5) and Peridinin chlorophyll protein

Zap70 is rate-limiting

Results

Identification of the reduced protein stability mutation in Zap70 and the resulting alteration in regulatory T-cell differentiation

The ENU-exposed C57BL/6 mice were bred to Foxp3GFP females to generate a standard F₂ intercross pedigree allowing screening of ENU mutants with altered numbers of Foxp3⁺ Treg cells in the blood. Within one pedigree, individuals were identified with an increased number of peripheral blood GFP⁺ Treg cells. Inter-crossing of affected individuals resulted in the reduced protein stability (rps) mutant strain, which consistently demonstrated increased numbers of Treg cells in the blood by 5–6 weeks of age (Fig. 1a). All-exon sequencing of affected individuals identified a C→T nucleotide substitution at nucleotide 36778405, which was confirmed by Sanger sequencing (Fig. 1b). This mutation resulted in an alanine to valine change at amino acid 243 in a region of the Zap70 protein sequence highly conserved across mammals (Fig. 1c) and partially conserved across related kinases in mice (Fig. 1d). The A243V change is located within the C-terminal SH2 domain, one of the two domains involved in the docking of Zap70 to phosphorylated immunoreceptor tyrosine-based activation motif on the TCR-ζ peptide (Fig. 1e–g).

Due to the sensitivity of T-cell differentiation to defects in TCR signalling, we next investigated the impact of the Zap70A243V variant on thymic differentiation. Unlike mice bearing a null allele of Zap70, Zap70rps mice did not have a major defect in positive selection. The overall thymic cellularity was unchanged in Zap70rps mice (data not shown) and the percentage of CD4⁺ CD8⁺ double-positive thymocytes remained intact, while the frequency of post-selection CD69⁺ double-positive thymocytes was reduced by ~20% (Fig. 2a–c). Similarly, a small impairment in lineage selection was observed, with a ~25% decline in the number of CD4⁺ single-positive thymocytes (Fig. 2d and Supplementary material, Fig. S1a) whereas CD8⁺ single-positive thymocytes were unchanged (Fig. 2e and Supplementary material, Fig. S1b). In addition, positive selection into the Foxp3³ regulatory T-cell lineage was reduced by ~30% in Zap70rps mice (Fig. 2f and Supplementary material, Fig. S1c). Non-complementation of the Zap70rps mutation was observed upon inter-crossing with the Zap70mrt strain (which is a severe hypomorph), as Zap70rps/mrt heterozygote mice bore defects in thymocyte differentiation ranging between that of the parental strains (Fig. 2b–f and Supplementary material, Fig. S1a–c). The mild defect in positive selection observed in the thymus was perpetuated in the periphery, with a ~25% drop in both CD4⁺ and CD8⁺ T cells in the spleen of Zap70rps mice relative to wild-type mice (Fig. 3a–c and Supplementary material, Fig. S1d, e) but similar total...
splenocyte numbers (data not shown). Again, the Zap70<sup>rps</sup> mutation was not complemented by the Zap70<sup>mrt</sup> mutation (Fig. 3a–c and Supplementary material, Fig. S1d, e), reinforcing the conclusion that T-cell defects in the rps strain are caused by the Zap70 A243V variant. Finally, consistent with other Zap70 hypomorphs<sup>9</sup> and the robust niche-filling capacity of Treg cells<sup>20</sup>, splenic Treg cell numbers rebounded to normal levels despite the ~30% reduction in thymic numbers, an effect which, when combined with the mild CD4<sup>+</sup> lymphopenia, resulted in a relative enrichment of Treg cells within CD4<sup>+</sup> T cells (Fig. 3d). In total numbers, the rebound was less obvious, but it was still apparent as the initial ~70% decline in Zap70<sup>rps</sup> thymic Treg cell number output ended up in only a ~30% decrease in peripheral numbers (Supplementary material, Fig. S1c,f). This relative enrichment

was probably responsible for the phenotype of increased number of peripheral blood GFP^+ Treg cells on which the rps strain was first identified and which remains constant with age (Supplementary material, Fig. S2).

The Zap70^A243V^ variant demonstrates reduced protein stability and impaired calcium signalling

To determine the mechanism of activity of the Zap70^rps^ mutation the relative expression of the Zap70^A243V^ variant was tested at the mRNA and protein levels. Complementary DNA was generated from sorted peripheral CD4^+ and CD8^+ T cells and the relative expression of Zap70 was assessed by quantitative PCR. No differences were observed between wild-type and Zap70^rps^ T cells, either CD4^+ or CD8^+, indicating that the rps mutation does not affect mRNA expression or longevity (Fig. 4a). To determine the effect of the Zap70^A243V^ variant on protein expression, Zap70 expression was measured by flow cytometry in CD4^+ and CD8^+ T cells of both the thymus and spleen. In the thymus, CD4^+ and CD8^+ single-positive T cells displayed a 50–70% reduction in Zap70 protein levels in Zap70^rps/mrt^ mice (Fig. 4b,c). By contrast, Zap70 expression was almost undetectable in the same population from Zap70^mrt^ mice, in which a major disruption to the catalytic site results in rapidly degraded
protein\(^{16}\). Compound heterozygotes between the Zap70\(^{rps}\) and Zap70\(^{mrt}\) strains showed a further \(~50\%\) reduction in Zap70 protein levels, to \(~30\%\) of wild-type levels (Fig. 4c). A reduction of \(~55\%\) in Zap70 protein level was also observed in the spleen of Zap70\(^{rps}\) mice, indicating that peripheral compensation mechanisms were not effective (Fig. 4d,e). Together, these results demonstrate that the rps mutation results in a Zap70 variant with reduced protein stability, titrating down the available Zap70 protein levels to \(~45\%\) across organs and lineages.

To determine the impact of reduced Zap70 levels on downstream signalling, CD4\(^{+}\) and CD8\(^{+}\) T cells from wild-type and Zap70\(^{rps}\) mice were stimulated in vitro for 24 hr. For both Zap70\(^{rps}\) CD4\(^{+}\) and CD8\(^{+}\) T cells, the up-regulation of early activation markers (CD25\(^{+}\) CD69\(^{+}\) T cells) was slightly reduced from that of wild-type cells (Fig. 5a), similar to that observed in Zap70\(^{mrt}\) mice, in which functional Zap70 is reduced by \(~45\%\). Notably, reliance on a single copy of Zap70\(^{rps}\) in combination with the severely hypomorphic Zap70\(^{mrt}\) allele (in Zap70\(^{rps/mrt}\) T cells) resulted in a more significant drop in T-cell activation, although still less than that observed in Zap70\(^{mrt}\) mice (Fig. 5a). To determine the quantity and quality of the immediate TCR signalling response, wild-type and Zap70\(^{rps}\) T cells were challenged in a Ca\(^{2+}\) flux assay. Following loading with Ca\(^{2+}\)-sensitive dye and recording of baseline fluorescence, wild-type and Zap70\(^{rps}\) CD4\(^{+}\) T cells showed significantly increased proportions of activated cells (Supplementary material, Fig. S3a). Individual Ca\(^{2+}\) signalling results showed a uniform response, excluding the possibility that the observed difference was due to population heterogeneity (Supplementary material, Fig. S3b).

Zap70 is rate-limiting
to wild-type CD4⁺ T cells, Zap70⁺⁺ CD4⁺ T cells showed a mild impairment of TCR signalling (Fig. 5b), with no significant reduction in peak intracellular Ca²⁺ (Fig. 5c), but a reduced duration of elevated intracellular Ca²⁺ (Fig. 5d). Hence, despite a reduction to ~55% of wild-type Zap70 protein levels, TCR signalling remained relatively unchanged in Zap70⁺⁺ T cells. These results were very similar to Zap70⁺⁻/mrt T cells, with ~45% of functional Zap70 levels. Strikingly, however, further reduction of functional Zap70 protein levels to ~30% of wild-type levels (observed in Zap70⁺⁻/mrt T cells) led to a complete blockade of effective Ca²⁺ flux in response to TCR stimulation (Fig. 5b–d). This discrepancy between Zap70⁺⁺ T cells and Zap70⁺⁻/mrt T cells demonstrates a non-linear relationship between Zap70 protein availability and TCR signalling events, as exemplified by the sigmoidal curve of Zap70 protein levels versus Ca²⁺ flux peaks (Fig. 5e) or versus general T-cell activation (Fig. 5f). Analysis of this relationship suggests a relatively narrow protein concentration range in which near-normal TCR signalling switches into an effectively non-functional state.

**Discussion**

In the present study, we characterized a novel Zap70 hypomorphic mutant mouse strain, Zap70⁺⁻ mice, in which an A243V change resulted in a 55% reduction in the Zap70 protein concentration. The phenotypic changes induced by ~50% reduction in Zap70 protein, either in Zap70⁺⁺ mice or mice heterozygous for the mrt mutation, proved relatively subtle, with a few notable exceptions. In both genetic contexts, TCR signalling remained largely intact, with normal peak intracellular Ca²⁺ achieved following TCR stimulation but a reduction in the duration of elevated intracellular Ca²⁺. This defect can be explained by the ~50% reduction in Zap70 protein levels in Zap70⁺⁺ T cells, as Zap70⁺⁻/mrt T cells, which have one normal fully-function copy of Zap70 and one severely hypomorphic and rapidly degraded copy of Zap70, have an indistinguishable phenotype. Nevertheless, it is conceivable that the A243V change also results in impaired function of the remaining protein. The two SH2 domains of Zap70 are involved in the binding of Zap70 to the TCR-ζ chain, following the phosphorylation of the immunoreceptor tyrosine-based activation motif by Lck. This binding releases Zap70 from its auto-inhibited conformation, allowing subsequent signal transduction.⁴ Crystal structure studies indicate that Y238 and K242 are closely associated with the phosphorytrosine of the immunoreceptor tyrosine-based activation motif peptide,²¹ suggesting that changes to the neighbouring 243 residue could impair docking of Zap70 to CD3ζ. Such a function would of necessity be minor, because otherwise the additive effects of reduced protein level and impaired protein function would be predicted to be greater than that of a similar reduction in protein level alone.

Regardless of the molecular mechanism by which Zap70 signalling is affected, the mild alteration in signalling capacity of Zap70⁺⁺ and Zap70⁺⁻/mrt T cells produced only small decreases in the TCR-dependent processes of positive selection and peripheral T-cell activation. The TCR-dependent process, which demonstrated the most substantial defect due to the 50% reduction in Zap70 protein levels, was the positive selection of Foxp3⁺ Treg cells. There are several reasonable hypotheses for this. First, thymic Foxp3 induction in Treg cell precursors is a positive selection event requiring an elevated level of TCR signalling²² and qualitatively different downstream mediators of signal transduction,²³ such that reduction of the kinase function may differentially impact Treg cells. Alternatively, Treg cells have been demonstrated to be dependent on a non-kinase function of Zap70 for activation of Rap1.²⁴ As Rap1 is involved in thymic Treg cell induction,²⁵,²⁶ it is plausible that partial loss of Zap70 protein has a stronger effect on Treg cell induction via reduction of both the kinase-dependent and Rap1-dependent Zap70 signalling pathways.

One interpretation of the resilience of TCR-dependent signalling to substantial losses in Zap70 protein could be that the Zap70 signalling pathway requires very little functional protein to signal. In this scenario it could be predicted that further reduction in Zap70 protein levels would lead to a progressive decline in total Zap70-dependent signalling. In contrast to this supposition, however, Zap70⁺⁻/mrt T cells demonstrated a profound defect in TCR signalling. In Zap70⁺⁻/mrt T cells the functional level of Zap70 protein was reduced to ~30% of normal levels, as a result of the compound effect of one allele of reduced protein stability producing half the normal Zap70 quotient and one allele (mrt) largely unable to produce functional levels of Zap70. The phenotype of these Zap70⁺⁻/mrt T cells was striking. Positive selection was essentially intact, however peripheral T-cell signalling was essentially absent. No intracellular Ca²⁺ flux was observed upon TCR-stimulation and even 24 hr of stimulation only resulted in very minor up-regulation of CD69 and CD25, consistent with just a ‘trickle’ of signalling capacity being left intact. It is tempting to speculate that the largely intact nature of positive selection in Zap70⁺⁻/mrt mice, in contrast to the defective peripheral signalling, is due to cooperation between remnant Zap70 with Syk. In human thymocytes, SYK is expressed at a higher level than in mouse thymocytes, and can substitute for Zap70 until SYK expression is lost in the periphery.²⁷ It is plausible that murine Syk, expressed at lower levels than SYK, cannot substitute for complete Zap70-deficiency but can substitute for the ~70% Zap70-deficiency observed in Zap70⁺⁻/mrt mice,²⁷ until Syk is lost in the periphery. Alternatively, this feature may simply emerge as a result of the lower signalling
requirement of positive selection versus peripheral T-cell activation. Regardless, it is striking that the reduction of Zap70 protein from 100% to 50% has almost no impact on TCR signalling, whereas further reduction from 50% to 30% results in an essentially complete blockade. This sigmoidal relationship between protein concentration and protein function constitutes a switch-like function, analogous to the dose–response function of TCR ligand affinity, which oscillates from ‘all on’ to ‘all off’ over a relatively small affinity range.

Finally, these observations serve as a case study for the emergent phenotypes that can develop in complex genetic

contexts. A recent study of publicly available exome sequencing data concluded that about 2% of the human population carries a rare, non-synonymous (protein sequence-altering) variant in any given gene, most of which are rare variants, i.e. found in < 1% of the population.⁴ Assuming ZAP70 is not exceptional, about four individuals per 10 000 will inherit compound heterozygous mutations in ZAP70. Our results here suggest that most of these combinations will have no observable phenotype, as the change induced by ~ 50% reduction in functional Zap70 in mice is well within the normal variation observed in humans. At the other end of the spectrum are ZAP70 deficiencies sufficient to cause SCID.⁶ Genetic defects within these extremes have been observed in humans, such as a case of hypomorphic Zap70, which resulted in late onset immunodeficiency.⁰ Notably, most of these mutations affect protein stability of Zap70, function in a similar manner to the tps mutation described here. Since we know from mouse studies that Zap70 mutations in the intermediate range produce an admixture of immunodeficiency and autoimmunity,⁹,¹² it is surprising that such cases have not been observed in humans, as genetic combinations that fall within the mid-range of the mutational spectrum should be more common than those at the extremes. To some degree this may be due to ascertainment bias in genetic diagnosis; however, the recent growth in all-exome sequencing approaches¹² should negate such effects. Our results here provide an alternative explanation for the absence of clinical phenotypes representative of intermediate defects: namely that the window for intermediate defects is narrow, such that most defects in Zap70 will fall either into the phenotypically normal or phenotypically null range. The extrapolation of these results on Zap70 to other genes would likewise provide an explanation for the vast majority of individuals having normal healthy phenotypes despite a surprisingly high genome-wide inherited mutational burden.
